This study focuses on six microalgae cultivated in open ponds in the Midwest Region of Brazil. Microalgae are a promising biomass source for biofuels, and this work evaluates their growth rates, lipid content, and fatty acid profiles. It is highlighted that Pseudokirchneriella subcapitata exhibits the highest growth rate (μmax), while Coelastrum sp. and P. subcapitata show the highest lipid levels. Palmitic acid is the main fatty acid accumulated in these microalgae. The study also analyzes factors influencing the outcomes of open pond cultivation.

**Keywords:** growth kinetic; composition; lipid profile.
Microalgas de lagoas abertas: Crescimento, Conteúdo de Lípidos e Ácidos Graxos

RESUMO
Este estudo foca em seis microalgas cultivadas em lagoas abertas na Região Centro-Oeste do Brasil. As microalgas são uma fonte promissora de biomassa para biocombustíveis, e este trabalho avalia suas taxas de crescimento, conteúdo de lípidos e perfis de ácidos graxos. Destaca-se que a Pseudokirchneriella subcapitata exibe a maior taxa de crescimento (μ_max), enquanto Coelastrum sp. e P. subcapitata apresentam os níveis mais altos de lípidos. O ácido palmítico é o principal ácido graxo acumulado nessas microalgas. O estudo também analisa fatores que influenciam nos resultados dos cultivos em lagoas abertas.

Palavras-chave: cinética de crescimento; composição; perfil lipídico.

Microalgae are photosynthetic microorganisms with high capacity of CO₂ absorption for the transformation into chemical energy. Using some nutrients such as potassium, phosphorus and nitrogen, they can be cultivated in open ponds or closed photobioreactors (Cuellar-Bermudez, Garcia-Perez, Rittmann, & Parra-Saldivar, 2015). Due to their low nutrient requirements, they can be grown in different agroindustrial and household wastes or low value-added fertilizers (Sipaúba-Tavares & Rocha, 2003; Dragone, Fernandes, Vicente, & Teixeira, 2010).

There are several applications of microalgae in the agro-industry and in the pharmaceutical and cosmetic industries, as well as great potential for the production of biofuels. The production of biodiesel from microalgae is viable due to their capacity to synthetize lipids. For this reason, the optimization of lipid accumulation by microalgae becomes important (Yen et al., 2013). The cultivation of microalgae in openponds is considered the best alternative for biomass production in large scale due to its easy construction, maintenance and operation (Park, Craggs, & Shilton, 2011).

In order to obtain increased productivities in sustainable production systems, it should be taken into account some factors, beyond the microalgae species utilized, e.g. geographic region, environment temperature, relative humidity of air, frequency of rainfalls, presence of sand and other pollutants, addition of carbon dioxide, price of the culture medium, pH, and the level of homogenization (Chisti, 2016; Silva & Fonseca, 2018).

In addition to the accumulation of lipids, the characterization of the saturated and unsaturated fatty acids synthetized is essential for the determination of biodiesel quality. This information can be used for a more accurate selection of a microalgae species for biodiesel production (Nascimento et al., 2013). The analysis of fatty acids is also important for the characterization of three important attributes of microbial communities: viable microbial biomass, community structure, and nutritional/physiological status (Piotrowska-Seget & Mrozik, 2003).
The aim of this work was to evaluate the physiology of 6 strains of microalgae (Chlorella sp., Coelastrum sp., Coleastrum sphaericum, Scenedesmus spinosos, Scenedesmus acuminatus and Pseudokirchneriella subcapitata) grew in open ponds in terms of kinetic parameters of growth and composition (moisture and lipid contents and fatty acids profile).

**Material and method**

The studied microalgae strains were *Chlorella* sp., *Coleastrum sphaericum*, *Scenedesmus acuminatus* and *Scenedesmus spinosos* and *Coleastrum sphaericum* and *Pseudokirchneriella subcapitata*, all previously isolated in the Brazilian Mid-Western region (Minillo, Godoy, & Fonseca, 2013). They were maintained in solid medium under refrigeration (4°C) in the absence of light at the Laboratory of Bioengineering from the Federal University of Grande Dourados.

Pre-inoculum was prepared in Chu-12 medium as described elsewhere (Sipaúba-Tavares & Rocha, 2003) in gallons of 9 L started with microalgae density of approximately 8 - 25 x 10⁴ cells mL⁻¹ at 25°C, light intensity of 10 Klux, 12 hours’ light photoperiods and aeration maintained by aquarium pumps, to obtain a higher cell density to later inoculate the open ponds. After 60 days, the 9L precultures were transferred to rectangular open ponds (3.5 x 1.0 x 0.6 m) filled with 2000L of NPK medium each, prepared by diluting 1 g of the chemical fertilizer N: P: K (20:5:20) for each liter of water (Sipaúba-Tavares & Rocha, 2003). The water was pumped into ponds from a local water well. In the ponds, the microalgae were exposed to environmental conditions (sunlight, temperature and rainfall) without control. For monitoring the growth of microalgae, samples (5 mL) were collected every 7 days to measure the absorbance at 600 nm (ABS₆₅₀) in duplicate (Demirel, Demirkaya, Imamoglu, & Dalay, 2016). This wave-length was chosen to avoid the interference caused by the production of pigments (Griffiths, Garcin, van Hille, & Harrison, 2011) to evaluate microbial cell growth in terms of optical density (OD) during 49 days of cultivation.

At the end of the cultivations, samples were collected from each pond,
centrifuged (5 g, 10 min.) and maintained in a drying oven with air circulation at 70°C up to constant weight to determine moisture. The dried biomasses were utilized to the quantification of lipids by the cold method (Bligh & Dyer, 1959) and fatty acids. All determinations were performed in triplicate.

For the characterization of fatty acids, the HCl transesterification was performed in methanol, in which the lipid extracts also extracted by the cold method were added of 500 μL of 5% HCl in methanol and the mixture was incubated for 2 hours at 100°C. After the reaction, 1.25 mL was added and the fatty acid methyl esters (FAME) were extracted with 1.25 mL of hexane (Martins, Yokoya, & Colepicolo, 2012). The FAME were determined by gas chromatography coupled to mass spectrometry (GC-MS), using a chromatograph (Agilent, model 7890A) equipped with a 30m x 0.25mm x 0.25m HP-5MS capillary column with helium entrapped as entrainment gas at a split ratio of 1:10. The analyses were performed at starting temperature of 180°C, applying heating rate of 10°C min⁻¹ up to 300°C. The detector and injector temperatures were 325 and 300°C, respectively. The analyses were performed in duplicate. The FAME were identified by comparing the retention time of sample’s constituents with a mixture of 19 fatty acid methyl ester standards, and by comparison with mass spectra of the NIST MS Search 2.0 library, included in the chromatograph’s software. Quantification was performed relative to an internal standard of methyl tricosanoate (23:0), following the method described elsewhere and maintaining a ratio of about 200:1 between the mass of oil and mass of internal standard (Menegazzo, Petenuci, & Fonseca, 2014).

Meteorological data of solar radiation (KWh m⁻² day⁻¹), temperature (°C), precipitation (mm), and relative humidity (RH) (%) of Dourados were obtained from Embrapa Centro-Oeste, Dourados, state Mato Grosso do Sul for the days corresponding to the cultivations in the open ponds. Temperature (°C) and pH were also obtained in situ.

The exponential growth phase was identified as the linear region on an In
ABS$_{600}$ vs. time plot for batch cultivation data. The maximum specific growth rate ($\mu_{\text{max}}$) was determined as the slope of this linear region. The doubling time (DT) was calculated by the quotient of the ln (2) by the $\mu_{\text{max}}$. The maximum biomass concentration was indicated by the maximum ABS$_{600}$ observed in each experiment (Nascimento, Silva, Gomez, & Fonseca, 2016). Measured absorbance values were converted into mass values using a linear relationship of optical density units per gram dry cell mass to calculate biomass and volumetric lipid productivities.

**RESULTS AND DISCUSSION**

During the cultivations, the average meteorological data were 26.2 ± 2.0ºC, 76.6 ± 8.0% of relative humidity of air, 12.6 ± 3.2 KWh m$^{-2}$ day$^{-1}$ of solar radiation, and precipitation ranging from 0 up to 44.6 mm (29 without any precipitation) (Figure 1). The temperature of the media in the open ponds was 30 ± 5 ºC and the pH ranged from 8.9 to 9.9 in the cultures (Table 1). This information is important to characterize the strains, e.g. in terms of productivities and lipid accumulation, and it is important to compare the obtained data with the literature at similar conditions.

Chisti (2016) numerated several recommendations for optimal cultivation in open ponds. Among the items are, the temperature between the 24 and 40ºC, cheap medium, and strains isolated in the region, which were according the suggested. However, there was no homogenization and control of level of pollutants and contaminants.

These two recommendations in fact influenced microalgae growth, e.g., it was noticed that part of the microalgal mud was composed by sand, brought by the wind. This material had to be removed by decanting before algae centrifugation. The same had to be done to obtain the correct absorbance measure along the samplings. The maximal absorbance obtained are shown in Table 1.

The growth kinetics for the six microalgae stains cultivated in open ponds with NPK medium during 49 days are shown in Figure 2. The growth profiles suggest a slow cell development. Growth rates are usually lower in open ponds.
compared to cultures in closed photobioreactors (Mata, Martins, & Caetano, 2010). In order to optimize growth in open ponds, a good homogenization is important. Control of the growth parameters, e.g. pH, light and nutrients is also desired (Park et al., 2011).

It was observed that *Pseudokirchneriella subcapitata* presented the highest maximum specific growth rate ($\mu_{\text{max}}$) and the shortest doubling time (DT), with values of 0.12 day$^{-1}$ and 5.40 days, respectively (Table 1). It was reported elsewhere an exponential growth rate of 0.11 to 0.13 day$^{-1}$ for *P. subcapitata* cultivated in NPK (Carvalho et al., 2012).

Regarding cell composition, moisture remained in the range of 90.33 to 94.77% for the different microalgae while the lipid content reached the higher content for *Coelastrum* sp. and *P. subcapitata*, which presented an average of 20% of lipids of the total dry weight (Table 1). In cultivation in open ponds, isolated microalgae *Graesiella* sp. WBG-1 accumulated up to 33.4% of lipids in its dry mass (Wen et al., 2016).

Although the growth rate is one of the crucial factors in the production of microalgae, it is important that the biomass present a high lipid yield (Stemmler, Massimi, & Kirkwood, 2016). Hannon, Gimpel, Tran, Rasala, and Mayfield (2010) suggested that strains with increased growth rates and high oil accumulation are better obtained by the selection of new species and genetic improvement.

**Figure 2.** Growth kinetics of *Chlorella* sp., *Pseudokirchneriella subcapitata*, *Coelastrum* sp., *Coelastrum sphaericum*, *Scenedesmus spinosus* and *Scenedesmus acuminatus* in open ponds during 49 days.

Oils were extracted from cellular content to determine the fatty acid composition. Palmitic acid (C16) was the predominant fatty acid in most microalgae lipid extracts (Table 2), which is in agreement with literature (Nascimento et al., 2013). A high accumulation of palmitic acid (69.71%) was described elsewhere for *Chlorella* sp. (Kalpish, Sharma, & Peer, 2012).

It was observed that the genus *Scenedesmus* presented a fatty acids profile
different from the other species. *S. spinosus* synthetized both polyunsaturated fatty acids (PUFAs) C21 and C25, while *S. acuminatus* presented the C25 in its composition (Table 2). The PUFAs present a series of special applications mainly as functional food, helping in the physical, physiological and mental development of the human organism (Martins, Suaiden, Piotto, & Barbosa, 2008).

The fatty acids content can be altered due to their accumulation or their use as an energy source. These changes occur through enzymes that act on the β-oxidation pathway, varying the fatty acid chains in two carbon units, which explains why most fatty acid chains are pairs (Voet, Voet, & Pratt, 2008; Taiz & Zeiger, 2008). Only the microalgae *S. acuminatus* and *S. spinosus* showed odd-chain fatty acids (Table 2), which is not usually observed. This happens in some plants and marine organisms, because the last cycle of β-oxidation provides propionyl-CoA that can be converted to succinyl-CoA, which enters the cycle of citric acid. This reaction requires the involvement of three enzymes: propionyl-CoA-carboxylase, methylmalonyl-CoA-racemase and methylmalonyl-CoA mutase (Voet et al., 2008). The question is that to achieve this transformation, it is necessary the coenzyme B₁₂, which is not found in bacteria (Voet et al., 2008; Taiz & Zeiger, 2008). It suggests that bacteria could have contaminated the open ponds, making this coenzyme available in the culture, which would have enabled the generation of fatty acids of odd chains.

Bacteria incorporate the fatty acids, mainly in phosphoslipids (Piotrowska-Seget & Mrozik, 2003). This characteristic is attributed to the ability to adapt to various extreme conditions (Sahu et al, 2013). Moreover, the chemical composition of microalgae alters when it is present in the presence of bacteria (Stemmler et al., 2016).

The evolution of the research in relation to the media, the way of cultivation, types of photobioreactor and later processes are of global interest so that the microalgae cultivation becomes an economically viable alternative for the obtaining of energy (Pereira et al., 2012).

**CONCLUSION**

Beyond microalgae species, several other factors influenced results from cultivations in open ponds, which were polluted with sand and contaminated with bacteria. However, it was possible to evaluate the kinetic parameters of six microalgae strains. The microalgae species that presented the higher maximum specific growth rate in open ponds was *Pseudokirchneriella subcapitata*. *Pseudokirchneriella subcapitata* and *Coelastrum* sp. presented the highest lipid content, but the genus *Scenedesmus* presented a differentiated fatty acids profile, including C21 and C25 polyunsaturated fatty acids, despite it was not clear if these compounds were resulting from contaminant bacteria.
